Abstract
We propose a method for optimizing the energy efficiency of software code running on small computing devices in the Internet of Things (IoT) that are powered exclusively by electricity harvested from ambient energy in the environment. Due to the weak and unstable nature of the energy source, it is challenging for developers to manually optimize the software code to deal with mismatch between the intermittent power supply and the computation demand. Our method overcomes the challenge by using a combination of three techniques. First, we use static program analysis to automatically identify opportunities for precomputation, i.e., computation that may be performed ahead of time as opposed to just in time. Second, we optimize the precomputation policy, i.e., a way to split and reorder steps of a computation task in the original software to match the intermittent power supply while satisfying a variety of system requirements; this is accomplished by formulating energy optimization as a constraint satisfiability problem and then solving the problem using an off-the-shelf SMT solver. Third, we use a state-of-the-art compiler platform (LLVM) to automate the program transformation to ensure that the optimized software code is correct by construction. We have evaluated our method on a large number of benchmark programs, which are C programs implementing secure communication protocols that are popular for energy-harvesting IoT devices. Our experimental results show that the method is efficient in optimizing all benchmark programs. Furthermore, the optimized programs significantly outperform the original programs in terms of energy efficiency and latency, and the overall improvement ranges from 2.3X to 36.7X.

1 Introduction
Energy harvesting is an environment-friendly technology that converts ambient energy in the environment such as sunlight, RF emission, and vibration into electricity [40, 37, 7, 32, 34, 31, 47]. When being used to power small computing devices in the Internet of Things (IoT), it avoids a main problem in the deployment of IoT at scale, which is the need to frequently change batteries [12]. Due to this reason, energy harvesting has been increasingly used in real-world deployment of IoT devices [43, 26]. However, due to the weak and unstable nature of the energy source, it is often challenging for developers to manually optimize the software code running on these IoT devices, to deal with problems caused by mismatch between the intermittent power supply and the often unpredictable computation demand.

Consider an IoT device powered by electricity harvested from sunlight as an example. During the day time, there may be significantly more harvested electricity than the combined

total of what can be stored in the supercapacitor of the device, and what can be consumed
by the software code running on the device. During the night time, however, the electricity
stored in the supercapacitor may be significantly less than what is needed by the software
code running on the device. In this context, an important research question is whether the
mismatch between supply and demand can be avoided, or at the very least mitigated by
rewriting the original software in such a way that, while the functionality of the software
remains the same, the overall energy efficiency is improved. Prior work [4, 5, 46] has
demonstrated the feasibility of this approach, based on two observations made for typical
energy-harvesting IoT devices.

The first observation is that, since the software on an IoT device only runs from time
to time, rather than continuously, the device may be idle when ambient energy in the
environment is abundant (e.g., sunlight during the day time) and yet the supercapacitor
used to store the harvested electricity is full. In such a case, the freely available energy in
the environment cannot be utilized. The second observation is that, in such an IoT device,
the most common computation tasks are collecting sensor data from time to time, and
encrypting these sensor data before sending them to some remote servers, e.g., servers in
the cloud. Thus, the most time-consuming and energy-consuming part of the computation
is the execution of the secure communication protocol. While the sensor data may have
to be collected just in time, a significant part of the secure communication protocol (e.g.,
computing security tokens needed for encrypting the sensor data) may be executed ahead of
time. This leads to the idea of leveraging the precomputation opportunities to utilize the
freely-available ambient energy in the environment.

Figure 1 illustrates how to optimize a computation task that must be executed during
the night time, when ambient energy is not available. While the original program \((P)\) has
to execute the entire computation task during the night time using electricity stored in the
supercapacitor, the optimized program \((P')\) executes a significant part of the task during
the day time, by harvesting the freely-available ambient energy that otherwise would have to
be wasted due to the storage limit of the supercapacitor. In some sense, the precomputation
performed during the day time transforms the solar energy to a digital form, called coupons,
and stores them in the non-volatile memory of the IoT device. During the night time, these
coupons are used to lower the energy cost of the remaining part of the computation task.
There are two main benefits. The first one is reduction in latency for the online computation part, since a significant portion of the computation task has been completed ahead of time. The second one is increase in the number of computation tasks that can be completed by the device. As a concrete example, Suslowicz et al. [46] show that, for a popular secure communication protocol based on one-time pad (OTP) [44], using precomputed OTPs for sensor data encryption reduces the energy cost of the online computation to 5% of the original energy cost needed for AES-OFB. Since the energy used to precompute OTPs is free, the overall energy reduction is close to 18 times (18X). To understand what this means, consider an IoT device that must complete 20 tasks during the day time and 20 tasks during the night time, but the electricity stored in the supercapacitor is only enough to support the completion of 2 tasks during the night time. Without precomputation, the device may be able to complete 20 tasks during the day time and only 2 tasks during the night time. By leveraging the coupons precomputed during the day time, the same device is able to complete 20 tasks and 20 partial tasks during the day time and finish off these 20 partial tasks during the night time.

However, to obtain the aforementioned benefits of precomputation, the current state of the art [4, 5, 46] requires a domain expert to optimize the software code manually, which is not only labor intensive but also error prone. Furthermore, the domain expert must be familiar with both the functionality of the software code and the energy characteristics of the hardware platform. The domain expert must also consider all of the system requirements while making the trade-off between energy reduction and increase in storage cost. In addition, manual optimization does not respond well to frequent software updates in practice: if the original software code is updated due to a bug fix or a security patch, there will be no easy way to update the manually-optimized software code.

To solve these problems, we propose a fully automated method for optimizing the energy efficiency of software running on energy-harvesting IoT devices. Toward this end, we must overcome three technical challenges. The first challenge is to identify the precomputation opportunities from the original software code automatically. The second challenge is to optimize the precomputation policy by exploiting the energy-storage trade-off and deciding which part of the computation task should be precomputed and which part of the computation task should be computed just in time. The third challenge is to automatically transform the software code to implement the energy optimization policy.

Figure 2 shows the overall flow of our method, which builds upon the state-of-the-art LLVM compiler platform [29]. Given the original program, our method takes three steps to produce the optimized program. In the first step, our method conducts a static analysis of the original program to identify precomputation opportunities, which are captured by \texttt{preSet} — the set of instructions in the program that may be computed ahead of time. In the second step, our method computes an optimal subset of \texttt{preSet} based on a variety of system constraints.
requirements, to minimize the energy cost while satisfying all requirements, including the storage limit of non-volatile memory used to save precomputation results. In the third step, our method leverages the LLVM compiler to generate the optimized program that has the ability to load the precomputation results from non-volatile memory and leverage them to speed up the just-in-time (online) computation part of the task. Finally, we evaluate the performance of the optimized programs on a popular hardware platform (MSP430 [24]) for energy-harvesting applications.

At the center of our method is a constraint based technique for optimizing the precomputation policy. The policy captures a solution to the complex optimization problem. The optimization problem is complex for several reasons. First, just because an instruction may be precomputed does not mean it is beneficial to precompute it, since precomputing does not always reduce energy cost; there is a trade-off between the cost of storing a precomputed coupon and the benefit of avoiding computing it directly. Second, decisions on which instructions to precompute cannot be made in isolation, since many of these instructions are dependent on each other; the precomputation policy has to consider all of the intra- and inter-procedural control- and data-flow dependencies in the program. Third, the size of the non-volatile memory used to store the precomputed coupons may not grow monotonically with the number of precomputed instructions, and furthermore, not all intermediate computation results in the program need to be stored as coupons in non-volatile memory. We will use concrete examples in Section 2 to illustrate these challenges and our proposed solution to overcome these challenges.

To demonstrate the effectiveness of our method, we have implemented and evaluated it on a large number of benchmark programs. Our implementation builds upon the LLVM compiler [29] and the Z3 SMT solver [11]. Specifically, we use LLVM to parse the original software code (written in the C language), conduct static program analysis, and generate the optimized software code; we use Z3 to solve the constraint satisfiability problems formulated by our method. Our tool was evaluated on 26 benchmark programs, which are C programs implementing popular secure communication protocols for IoT devices; in total, they have 31,113 lines of C code (LoC). The LoC of each program ranges from 339 to 1,572. Our target hardware platform is MSP430 [24], a family of ultra-low-power microcontroller units (MCUs) popular for energy-harvesting IoT applications.

Our experimental results are promising. In terms of the efficiency of our method, the experimental evaluation shows that all of the benchmark programs can be optimized by our tool quickly, and the optimization time is always limited to a few seconds. In terms of the effectiveness of our method, the experimental evaluation shows that all of the optimized programs significantly outperform the original programs in terms of energy efficiency and latency. Specifically, reduction in the overall energy cost ranges from 2.3X to 36.7X.

To summarize, this paper makes the following contributions:

- We propose a compiler based technique for automatically identifying precomputation opportunities in the software code using static analysis and then exploiting these opportunities using a semantic-preserving program transformation.
- We formulate energy optimization as a constraint satisfiability problem and solve the problem using an off-the-shelf SMT solver; this approach is not only flexible but also efficient in minimizing the energy cost while satisfying a variety of system requirements.
- We implement the method using a state-of-the-art compiler (LLVM) and a popular hardware platform (MSP430) for energy-harvesting applications, and demonstrate the effectiveness on a large number of benchmark programs.
2 Background

We review the technical background, including the characteristics of the hardware platform (MSP430) and an example software program to motivate our approach.

2.1 The Hardware Platform

MSP430 is a family of microcontroller units (MCUs) based on a 16-bit RISC instruction set architecture. Due to our focus on energy-harvesting applications, we are concerned with a subset of MSP430 MCUs that have the main memory partitioned into the volatile part and the non-volatile part. Depending on the application, data may be stored either in volatile memory or in non-volatile memory. These MCUs have a large number of configuration parameters, including sixteen nominal frequencies in the range 0.06 MHz to 16 MHz. For example, they may run in a low-power mode at the clock frequency of 1 MHz and the supply voltage of 1.8V, or in a high-performance mode at the clock frequency of 16 MHz and the supply voltage of 2.9V.

Since MSP430 MCUs are designed for low-power applications, they have no instruction cache or data cache. Unlike high-end CPUs widely used in servers and desktops, which routinely use advanced frequency or voltage scaling techniques, low-power MCUs such as MSP430 have significantly simpler energy models: fluctuations in power consumption are primarily due to the dynamics in supply voltage and clock speed. In fact, power consumption may be modeled using a non-linear function derived by empirically measuring the impact of varying voltage supplies and clock speeds on the power consumption of real hardware for all possible MCU configurations [2].

Accurate compile-time analysis for energy prediction [10, 3] is well studied topic for transiently powered computing systems [2], where software developers need to know the worst-case energy cost of a computation task, to maximize the software’s utilization of the electricity harvested from the environment and to ensure timely checkpointing of the program state before loss of power. The accuracy of such compile-time analysis techniques have come close to direct hardware emulation. While direct hardware emulation [20, 8] offers the highest possible accuracy due to the direct measurement on target hardware, it does not offer the level of convenience and automation desired at the early stages of software development.

In this work, we evaluate our proposed method using MSPSim [15, 38], which is a popular compile-time analysis tool for MSP430. Specifically, we use MSPSim to compute and then compare the latency and energy cost of all benchmark programs, before and after our constraint-based optimization. MSPSim allows the developer to tag a piece of the software code for which energy consumption will be estimated. It does this by first generating the assembly code for MSP430, and then analyzing the assembly code to compute the number of MCU cycles needed to execute each basic block. Then, it estimates the energy consumption of each basic block based on the empirically derived energy model, the supply voltage, and the clock speed of the device.

At a high level, the energy consumption depends on the supply voltage as well as the electrical current for a given resistance of the MCU, the latter of which in turn depends on the supply voltage and the clock speed. For more details on the energy model used in such compile-time analysis tools, refer to Ahmed et al. [2].
Figure 3 An example program that invokes the W-OTS routine when \textit{msg} is ready. Here, \textit{msg\_ready} and \textit{msg} are global variables updated by other functions not presented in this figure. For \textit{wots()}, \textit{msg} is the input while \textit{pub\_key} and \textit{sig} are the output. For \textit{gen\_key()}, both \textit{priv\_key} and \textit{pub\_key} are the output. For \textit{sign()}, \textit{msg} and \textit{priv\_key} are the input while \textit{sig} is the output.

2.2 The Software Program

Figure 3 shows the program, where \textit{ISR} stands for the interrupt service routine. Assume that the routine is triggered periodically by a timer. Whenever the input data stored in \textit{msg} is ready, the subroutine \textit{wots()} is invoked (Line 3). It implements a hash-based cryptographic primitive called the Winternitz one-time signature (W-OTS \cite{39}). Here, \textit{msg} is the input, while \textit{pub\_key} and \textit{sig} are the output. After generating the output, the device sends the pair (\textit{pub\_key},\textit{sig}) to a verifier on a remote server (Line 4).

Let us take a closer look at the routine \textit{wots()} defined in Lines 7-10, which consists of two subroutines. The subroutine \textit{gen\_key()} is invoked first, which returns a fresh pair of the private key \textit{priv\_key} and the public key \textit{pub\_key} as output. Then, the subroutine \textit{sign()} is invoked, which takes \textit{msg} and \textit{priv\_key} as input and returns the signature \textit{sig} as output.

Since the input \textit{msg} may be sensor data generated \textit{just in time}, in the context of our work, it is called an \textit{online} input. Furthermore, any output or intermediate variable that is control- or data-dependent on the \textit{online} input must be computed \textit{just in time}. In contrast, results that do not depend on the \textit{online} input may be computed \textit{ahead of time}.

2.2.1 The Original Program

Figure 4 shows the definitions of the two subroutines invoked by \textit{wots()}. The subroutine \textit{sign()} in Line 7 takes \textit{msg} and \textit{priv\_key} as input and returns \textit{sig} as output. While \textit{msg} is an \textit{online} input, \textit{priv\_key} is computed by the subroutine \textit{gen\_key()}. In this sense, \textit{sign()} depends on \textit{gen\_key()}.

The subroutine \textit{gen\_key()} does not have any input, and thus does not depend on any other subroutine. More importantly, it does not depend on any \textit{online} input. Thus, \textit{gen\_key()} may be executed ahead of time, e.g., whenever ambient energy is available to the harvester. It means that both \textit{priv\_key} and \textit{pub\_key} may be computed ahead of time. These precomputed keys may be saved to non-volatile memory as \textit{coupons}, and later used by \textit{sign()} to encrypt the \textit{online} input \textit{msg}.

Although the subroutine \textit{sign()} partially depends on the \textit{online} input \textit{msg}, and thus cannot be executed ahead of time \textit{in its entirety}, a significant part of the function body can still be executed ahead of time. Specifically, the subroutine \textit{gen\_random()} does not depend on the \textit{online} input at all, and the subroutine \textit{memcpy()} depends only on \textit{rand} computed by \textit{gen\_random()}; thus, both subroutines can be computed ahead of time.

If we continue this analysis by going down the chain of function calls, we may identify

```c
gen_key(priv_key, pub_key) {
    gen_random(priv_key, PRIV_KEY_SIZE);
    sha256_init(&keyHash);
    sha256_update(&keyHash, priv_key, PRIV_KEY_SIZE);
    sha256_final(&keyHash, pub_key);
}

sign(msg, priv_key, sig) {
    gen_random(rand, SHA_BLK_SIZE);
    memcpy(sig, rand, SHA_BLK_SIZE);
    message_digest(digest_bits, sig, msg);
    gen_sig(sig, priv_key, digest_bits);
}
```

Figure 4 Definitions of the subroutines used by the W-OTS routine.

```c
wots_precom(msg, pub_key, sig) {
    //NVM-Store <priv_key, pub_key> to coupon pool;
    sign_precom(msg, priv_key, sig);
}

wots_online(msg, pub_key, sig) {
    //NVM-Load <priv_key, pub_key> from coupon pool;
    sign_online(msg, priv_key, sig);
}

gen_key(priv_key, pub_key) {
    gen_random(priv_key, PRIV_KEY_SIZE);
    sha256_init(&keyHash);
    sha256_update(&keyHash, priv_key, PRIV_KEY_SIZE);
    sha256_final(&keyHash, pub_key);
}

sign_precom(msg, priv_key, sig) {
    gen_random(rand, SHA_BLK_SIZE);
    memcpy(sig, rand, SHA_BLK_SIZE);
    //NVM-Store <sig> to coupon pool;
}

sign_online(msg, priv_key, sig) {
    //NVM-Load <sig> from coupon pool;
    message_digest(digest_bits, sig, msg);
    gen_sig(sig, priv_key, digest_bits);
}
```

Figure 5 Conceptually, the program may be divided into two parts (precom and online).

more precomputation opportunities, e.g., instructions inside subroutines `message_digest()` and `gen_sig()`. In our proposed method, this process of systematically identifying these precomputation opportunities is automated, based on static program analysis techniques.

2.2.2 Dividing into Two Parts

Based on the precomputation opportunities identified by static program analysis, the original program may be divided into two parts: the precomputation (precom) part and the online computation (online) part, as shown by Figure 5.

Specifically, top-level routine `wots()` is divided into `wots_precom()` and `wots_online()`. The subroutine `wots_precom()` may be invoked ahead of time, since it does not depend on the `online` input `msg` at all. After invoking `gen_key()` to compute the public and private keys, denoted `priv_key` and `pub_key`, it stores them in non-volatile memory (Line 3). Then, it invokes `sign_precom()` defined in Line 16, to compute the signature `sig`, before storing it.
in non-volatile memory (Line 19).

The subroutine \texttt{wots\_online()} must be invoked just in time, since it depends on the
\texttt{online} input \texttt{msg}. This subroutine first loads the precomputed keys \texttt{priv\_key} and \texttt{pub\_key}
from non-volatile memory (Line 7) and then invokes \texttt{sign\_online()} defined in Line 21.
Inside \texttt{sign\_online()}, the precomputed signature \texttt{sig} is loaded from non-volatile memory
(Line 22) and then used together with \texttt{msg} and \texttt{priv\_key} to compute the final version of the
signature \texttt{sig} (Lines 23-24).

According to our experimental evaluation (presented in Section 7), on low-power devices
such as MSP430, this kind of precomputation can reduce the energy cost of running W-OTS
to 42.89\% of the original cost. In other words, it is more than 2.3\X reduction. Thus, with
the same amount of electricity used to run the original W-OTS program once, now, we can
run the optimized W-OTS program 2.3 times.

### 2.2.3 Challenges in Optimization

Just because an instruction may be precomputed (i.e., it does not depend on any \texttt{online}
input) does not mean that it is beneficial to do so, since precomputation does not always
reduce the energy cost. Depending on the hardware platform, it is possible for the cost of
storing and retrieving the precomputed result to outweigh the benefit.

For example, in Line 18 of Figure 5, if we choose to precompute \texttt{memcpy()} inside the
subroutine \texttt{sign()}, the energy cost of loading the precomputed coupon \texttt{sig} from non-volatile
memory may be slightly higher than the energy needed to execute \texttt{memcpy()} directly. If that
is the case, precomputation should be avoided.

In general, whether precomputation is beneficial or not depends on both the software
and the hardware. Consider the characteristics of volatile and non-volatile memory used
in MSP430FR5969 \[24] as an example. According to the hardware data-sheet, at the clock
frequency of 8 MHz, the energy per clock cycle is 0.33 nJ for volatile memory, but is 0.42 nJ
for non-volatile memory. This kind of information must be considered during optimization.

Furthermore, decisions on which instructions to precompute cannot be made in isolation,
since many of these instructions are dependent on each other according to the control and
data flows of the program. Therefore, we must consider all of the intra- and inter-procedural
control- and data-flow dependencies in the program while performing the optimization.

These are the reasons why we propose the constraint based method. By first formulating
it as a constraint satisfiability problem and then solving the problem using an off-the-shelf
SMT solver, we are able to optimally partition the program into the precomputation part
and the online computation part, while satisfying a variety of requirements coming from the
hardware platform as well as the software program.

### 2.2.4 The Optimized Program

To keep the size of the optimized program small, we do not actually divide the program into
two parts as shown by Figure 5. Instead, we keep the two parts in a single program, and try
to retain the original control and data flows of the program as much as possible.

Figure 6 illustrates our method by showing the optimized program for the original program
in Figure 4. Our method adds two parameters, \texttt{precom\_flag} and \texttt{online\_flag}, to represent
the following three use cases:

- When \texttt{(precom\_flag,online\_flag)} = \texttt{(true,false)}, it does precomputation.
- When \texttt{(precom\_flag,online\_flag)} = \texttt{(false,true)}, it does online computation.
- When \texttt{(precom\_flag,online\_flag)} = \texttt{(true,true)}, it acts as the original program.
Y. Li and C. Wang

wots_trans(msg, pub_key, sig, precom_flag, online_flag) {
  if (precom_flag == true)
    gen_key(priv_key, pub_key);
  if (!online_flag)
    //NVM-Store <priv_key, pub_key> to coupon pool;
  if (!precom_flag)
    //NVM-Load <priv_key, pub_key> from coupon pool;
  sign_trans(msg, priv_key, sig, precom_flag, online_flag);
}

sign_trans(msg, priv_key, sig, precom_flag, online_flag) {
  if (precom_flag == true) {
    gen_random(rand, SHA_BLK_SIZE);
    memcpy(sig, rand, SHA_BLK_SIZE);
  }
  if (!online_flag)
    //NVM-Store <sig> to coupon pool;
  if (!precom_flag)
    //NVM-Load <sig> from coupon pool;
  if (online_flag == true) {
    message_digest(digest_bits, sig, msg);
    gen_sig(sig, priv_key, digest_bits);
  }
}

Figure 6 Merging the two parts into a single optimized W-OTS routine.

__interrupt void ISR(void) {
  if(!msg_ready) {
    if (ambient_energy_available)
      wots_trans(NULL, pub_key, sig, true, false); //precom (part 1)
  }
  else {
    if (!ambient_energy_available)
      wots_trans(msg, pub_key, sig, false, true); //online (part 2)
    else
      wots_trans(msg, pub_key, sig, true, true); //combined (part 1 + part 2)
    //Send the pair <pub_key, sig> to verifier;
  }
}

Figure 7 Different scenarios for invoking the optimized W-OTS routine.

Compared to the original program in Figure 4, the only difference in Figure 6 is the addition of two flags as input parameters of some of the subroutines, together with the if-conditions that indicate whether a code block should be executed during the precomputation step or during the online computation step.

Figure 7 shows how the optimized program may be invoked by the interrupt service routine. Unlike what is shown in Figure 3, here, precomputation is performed when msg is not available but ambient energy is available (Line 4). When msg is available, it depends on whether ambient energy is still available. If ambient energy is not available, then online computation is performed (Line 8). However, if ambient energy is available, operations that access non-volatile memory will be skipped, which makes wots_trans() behaves exactly the same as the original program (Line 10).
3 Overview of Our Method

We first present our top-level procedure and then outline the main technical challenges.

3.1 The Top-Level Procedure

Algorithm 1 shows our top-level procedure. The input consists of the original program ($P$), the online input ($OI$) of the program, and the system constraint ($C$). The output is the optimized program ($P'$).

```
Algorithm 1  The top-level procedure of our method.
input : original program $P$, online input $OI$, system constraint $C$
output : optimized program $P'$
1 $PDG \leftarrow \text{ConstructPDG}(P)$;
2 $\text{preSet} \leftarrow \text{IdentifyPreSet}(P, PDG, OI)$;
3 $\text{preSet}^* \leftarrow \text{OptimizePreSet}(\text{preSet}, PDG, C)$;
4 $P' \leftarrow \text{Transform}(P, PDG, \text{preSet}^*)$;
5 return $P'$
```

For the running example in Figure 3, where the entry function is $\text{wots()}$, the online input is $OI = \{\text{msg}\}$, since msg is the only input value that must be ready at run time. $C$ consists of a set of platform-dependent requirements, e.g., the size of non-volatile memory used to store coupons must be limited to $\leq 256$ KB.

In Algorithm 1, our method first constructs a program dependency graph (PDG) for the program $P$. Then, our method uses the PDG and the set of variables in the online input $OI$ to compute $\text{preSet}$, which is the set of instructions in $P$ that may be precomputed. Next, it computes $\text{preSet}^*$, which is a subset of $\text{preSet}$ that represents the optimal solution to the constraint satisfiability problem. Finally, our method transforms the program $P$ to a new program $P'$ based on the information stored in both $PDG$ and $\text{preSet}^*$.

Before presenting the detailed algorithms inside the subroutines $\text{IdentifyPreSet()}$, $\text{OptimizePreSet()}$ and $\text{Transform()}$, we point out the main technical challenges.

3.2 The Technical Challenges

The first challenge, related to the subroutine $\text{IdentifyPreSet()}$, is the complex nature of the program dependency analysis. In Figures 3 and 4, for example, we observe that the subroutine $\text{sign()}$ depends on $\text{gen_key()}$; furthermore, the subroutine $\text{gen_sig()}$ invoked by $\text{sign()}$ depends on $\text{gen_key()}$. It means that we must consider not only dependencies of instructions within each subroutine, but also dependencies between subroutines.

Moreover, since we aim to transform individual functions of the original program without changing the overall function call structure, each function must be analyzed in all of its calling contexts, to figure out how the function body should be optimized. In Figure 4, for example, it means that since $\text{gen_random()}$ is called by both $\text{gen_key()}$ and $\text{sign()}$, we must consider both calling contexts.

The second challenge, related to the subroutine $\text{OptimizePreSet()}$, is optimizing the precomputation policy while satisfying a variety of system constraints. Given $\text{preSet}$ (which is the set of instructions that may be computed), we need to identify a proper subset. For the MSP430 family of microcontroller units, a limiting factor may be the capacity of non-volatile memory, only part of which may be dedicated to coupon storage. In general, this is a
non-linear optimization problem, e.g., the storage cost may not increase linearly, or even
monotonically, as more instructions are added to the precomputation set.

In Figure 4, for example, the cost of precomputing only Lines 2-4 is \( \text{size}(\text{priv_key}) + \text{size}(\text{keyHash}) \), where \( \text{size}() \) denotes the size of non-volatile memory for storing the value. However, the cost of precomputing Lines 2-5 is \( \text{size}(\text{priv_key}) + \text{size}(\text{pub_key}) \), because \( \text{keyHash} \) no longer needs to be stored in non-volatile memory. Since \( \text{size}(\text{pub_key}) \) is much smaller than \( \text{size}(\text{keyHash}) \) in the W-OTS example, this means that precomputing one more line actually decreases the overall storage cost.

The third challenge, related to the subroutine \( \text{Transform()} \), is the difficulty in preserving functional equivalence while allowing the program to change its execution order and data flow. For example, if we want to precompute Line 2 and Line 8 in Figure 4, we must modify the program to ensure that the original execution order (Line \( l_3 \) executed before Line \( l_8 \)) changes to the new execution order (\( l_8 \) executed before \( l_3 \)); at the same time, we must ensure that the original data flow \( \text{priv_key}(l_2) - l_3, l_4, l_5 - l_8 \) changes to \( \text{priv_key}(l_2) - l_8 - l_3, l_4, l_5 \).

While doing so for this particular example may seem easy, in general, maintaining functional equivalence during such program transformation can be challenging.

4 Identifying the Precomputation Set

In this section, we present our method for computing \( \text{preSet} \), as shown in Algorithm 2. It takes the program \( P \), the program dependency graph \( \text{PDG} \), and the online input \( \text{OI} \) as parameters, and return \( \text{preSet} \) as output.

**Algorithm 2** The subroutine \( \text{IdentifyPreSet}(P, \text{PDG}, \text{OI}) \).

1. Let \( \text{pred}(\text{inst}) \) be a predecessor node of instruction \( \text{inst} \) in the \( \text{PDG} \).
2. \( \text{preSet} \leftarrow \{ \text{elementary instructions in } P \} \cup (\{ \text{input parameters of } P \} \setminus \text{OI}) \)
3. while \( \exists \text{inst} \in \text{preSet} \text{ and } \text{pred}(\text{inst}) \notin \text{preSet} \) do
   1. remove \( \text{inst} \) from \( \text{preSet} \)
4. end
5. return \( \text{preSet} \)

Recall that \( \text{preSet} \) is the set of instructions in \( P \) that may be computed ahead of time. Internally, our method computes \( \text{preSet} \) in two steps. The first step is identifying the inter-procedural dependencies related to the online input \( \text{OI} \). These dependencies will be captured by function such as \( \text{pred}(\text{inst}) \), \( \text{preds}(\text{inst}) \), and \( \text{succs}(\text{inst}) \), which returns the predecessor, set of predecessors, and set of successors of an instruction \( \text{inst} \), respectively. The second step is leveraging these dependencies to compute the instructions in \( \text{preSet} \).

In Algorithm 2, initially, \( \text{preSet} \) consists of all the \textit{elementary instructions} and input parameters of \( P \), except for the ones in \( \text{OI} \). Variables in \( \text{OI} \) are excluded because they are the \textit{online} variables. Here, an \textit{elementary instruction} means that during our analysis the instruction will be treated as a whole. First, non-function-call instructions are elementary instructions. Second, when an instruction invokes a function call, whether it is elementary depends on how many times the function is called. If the function is called only once, it is not treated as an elementary instruction; instead, we enter the function body to try to identify more precomputation opportunities. But if the function is called from multiple sites, we treat each call as an elementary instruction, meaning that we do not enter the function body to explore further. This is a reasonable compromise since, when a function is called from...
4.1 Inter-Procedural Dependencies

To identify the maximum set of instructions in Preset using Algorithm 2, we need the dependencies associated with the online input OI. These dependencies are more complex than what are typically available in the compiler. For example, by default, LLVM provides the control- and data-dependencies between instructions only within each function. However, we need to know dependencies not only within each function, but also between functions.

To identify inter-procedural dependencies, we first compute a PDG for each function, together with a call graph that represents the caller-callee relations of all functions in the program. We also extend LLVM to add the ability to determine whether a function call may change the content of a function parameter passed by reference or the value of a global variable. This is accomplished by traversing paths in the call graph and analyzing all of the functions involved in the path.

Next, we analyze the inter-procedural dependencies in a bottom-up fashion, according to the function call graph. Consider the example of the following two functions: \texttt{fun1(arg1)} and \texttt{fun2(arg2, arg3)}, where the input parameter \texttt{arg1} of \texttt{fun1()} depends on the output parameter \texttt{arg2} of \texttt{fun2()}. Assume that \texttt{arg3} is also an output parameter of \texttt{fun2()}.

Assume that inside the function \texttt{fun2()} there is an instruction \( I \) that computes the value of \texttt{arg2}. Furthermore, inside \texttt{fun1()} there is an instruction \( I' \) that computes the value of \texttt{arg1}. While all intra-procedural dependencies may be computed in isolation, we must combine them to identify the inter-procedural dependencies, such as the dependency between \( I' \) of \texttt{fun1()} and \( I \) of \texttt{fun2()}.

Figure 8 shows a more concrete example, where the PDGs are constructed for the code snippets in Figures 3 and 4. Consider the edge \( 2 \rightarrow 11 \) in Figure 8 (b), which represents the dependency between the instruction at Line 2 and the instruction at Line 11 of the program in Figure 4. It means the input parameter \texttt{priv_key} used by \texttt{sign()} at Line 11 comes from the output parameter \texttt{priv_key} of \texttt{gen_key()} at Line 2.

With the inter-procedural dependencies, we can define the notion of a predecessor, denoted by \texttt{pred()}. For example, in Figure 8 (b), due to the edge \( 2 \rightarrow 11 \), we say that the instruction at Line 2 is a predecessor of the instruction at Line 11 inside the program shown by Figure 4.
4.2 Iteratively Computing \textit{preSet}  

Using the notion of a \textit{predecessor} of an instruction \textit{inst}, denoted \textit{pred}(\textit{inst}), our method computes the \textit{preSet} according to the while-loop in Algorithm 2.

It starts with all elementary instructions and input parameters that are not in \textit{OI}. Then, it removes any instruction (\textit{inst}) that has a predecessor \textit{pred}(\textit{inst}) not in \textit{preSet}. There are two possible reasons why \textit{pred}(\textit{inst}) is not in \textit{preSet}: either it is in \textit{OI}, or during the previous iteration, it has been removed from \textit{preSet}. Thus, it is a fixed-point computation.

The correctness of the fixed-point computation can be understood as follows: By definition, the instruction \textit{inst} depends on its predecessor \textit{pred}(\textit{inst}). If \textit{pred}(\textit{inst}) \notin \textit{preSet}, meaning the predecessor instruction cannot be precomputed, then the instruction \textit{inst} itself cannot be precomputed either.

As an example, consider the instructions of W-OTS in Figure 4. For ease of presentation, we use \textit{l}_i to represent the instruction at Line \textit{i}, and we treat all instructions in this program as elementary instructions. Initially, we have \textit{preSet} = \{\textit{l}_2 - \textit{l}_5, \textit{l}_8 - \textit{l}_{11}\}.

Next, we check if any of these instructions should be removed, based on the \textit{predecessor} relation shown in Figure 8. The instruction \textit{l}_{10} should be removed, since its predecessor (\textit{msg\_ready}) is not in \textit{preSet}. Thus, we remove \textit{l}_{10} from \textit{preSet}.

The removal of \textit{l}_{10} leads to the removal of \textit{l}_{11} during the next iteration, since \textit{l}_{10} is the predecessor of \textit{l}_{11}. If \textit{l}_{11} cannot be precomputed, then \textit{l}_{10} cannot be precomputed either.

Thus, in the end, we have \textit{preSet} = \{\textit{l}_2 - \textit{l}_5, \textit{l}_8 - \textit{l}_9\}.

\textbf{Theorem 1.} Our method for computing \textit{preSet} is sound in that, for all \textit{inst} \in \textit{preSet}, there is guarantee that the instruction (\textit{inst}) can indeed be computed ahead of time.

Proof: An instruction \textit{inst} remains in \textit{preSet} only if all of its predecessors are also in \textit{preSet}. As long as the inter-procedural dependencies represented by the PDGs are an over-approximation of the actual dependencies, the \textit{preSet} is guaranteed to be an under-approximation of the set of instructions that may be computed ahead of time.

The reason why it is an under-approximation because \textit{pred}(\textit{inst}) is an over-approximation of the predecessors. Whenever \textit{pred}(\textit{inst}) \notin \textit{preSet}, Algorithm 2 removes \textit{inst} from \textit{preSet}.

The reason why \textit{pred}(\textit{inst}) is an over-approximation is due to the nature of PDG-based analysis techniques. Refer to Horwitz et al. \cite{22} and Reps et al. \cite{41} for more information.

\hfill \blacktriangleleft

4.2.1 Handling Loops

Similar to all other PDG-based analysis techniques \cite{22, 41}, our method has no problem in handling software code with loops. In most of the practical cases, computing the \textit{predecessor} is straightforward. For example, the function call \texttt{sign()} at Line 9 in Figure 3 requires \texttt{msg} and \texttt{priv\_key} to be available. These dependencies are due to data flow represented by the \textit{definition-use} correspondence.

However, there are cases where definitions and uses do not have one-to-one mapping. For example, in Figure 9, the variable \texttt{i} used at Line 7 may be defined at either Line 2 or Line 5. In the context of data-flow analysis, the definition at Line 5 does not \texttt{kill} the definition at Line 2. Therefore, it may or may not be necessary to precompute Line 3-6 in order to precompute Line 7, for example, if \texttt{CNT[len-1]}!=\texttt{0xff}.

Since our method is designed to be sound, to ensure that the optimized program is correct for all input values, it is allowed to \textit{first} over-approximate the predecessor relation, and then conservatively assume that an instruction can be precomputed \textit{only} if all of its predecessors can be precomputed.
void increment_CNT(BYTE *CNT, int len){
    int i = len;
    while ((i > 0) && (CNT[i-1] == 0xff)){
        CNT[i-1] = 0;
        i--;
    }
    if (i) {
        CNT[i-1]++;}
}

Figure 9 Code snippet taken from the benchmark program named AES-CTR.

5 Optimizing the Precomputation Set

While all instructions in preSet have been identified at this moment, it may not be beneficial to compute all of them ahead of time. In this section, we present our method for computing an optimal subset preSet* ⊆ preSet. This is implemented in OptimizePreSet(preSet, PDG, C), where C is the system constraint. Besides the characteristics of the hardware platform, such as the size of non-volatile memory, it also includes the characteristics of the software program, such as how often the encrypted sensor data must be transmitted to the remote server.

5.1 The Motivation

We use an example to illustrate the complex nature of the optimization problem, which in turn motivates our development of the constraint based solution.

Consider the W-OTS program in Figure 4 and its PDGs in Figure 8 (b). According to Algorithm 2, preSet = {l2 - l5, l8 - l9}. Since these instructions do not depend on the online input msg, in theory, they may be precomputed as many times as possible. However, due to the storage capacity, in practice, the number has to be bounded.

Let Si be a subset of preSet, called a precomputation choice, and mi be the maximum number of times that Si may be precomputed. Since each time Si produces an intermediate result, or coupon, we also call mi the coupon count (number of copies of this particular coupon). Let NVM(Si) be the storage cost for this coupon, and maxNVM be the storage capacity of the entire device. We use the maximal allowed NVM size to avoid the potential risk of running out of NVM. One precomputation choice for the running example is represented by S1 = {l2}, where m1 ≤ maxNVM/NVM(S1). That is, the coupon count m1 is bounded only by the storage capacity.

Below are some other precomputation choices:

S2 = {l2 - l5, l8}, where m2 ≤ maxNVM/NVM(S2)
S3 = {l2 - l5, l8 - l9}, where m3 ≤ maxNVM/NVM(S3)

... Let n = |preSet|, the number of precomputation choices is \( \Sigma_{i=1}^{n} \binom{i}{*} \). Since it causes combinatorial explosion, we cannot afford to enumerate them to decide which one is optimal.

The number of precomputation choices can be even higher than \( \Sigma_{i=1}^{n} \binom{i}{*} \). For example, when S4a = {l2 - l5} and S4b = {l2 - l5, l8 - l9}, if we allow the coupon counts m4a and m4b to have different values, they would be bounded only by the constraint m4a × NVM(S4a) + m4b × NVM(S4b) ≤ maxNVM. This leads to another combinatorial explosion.

While making a precomputation choice, we cannot consider instructions in isolation, since they may be dependent on each other. For example, precomputing one instruction may...
require precomputing another instruction. Recall that in the example program shown in
Figure 4, we cannot precompute $l_5$ without precomputing $l_4$, because there is dependency
from $l_4$ to $l_5$. In other words, $l_4 = \text{pred}(l_5)$.

All these challenges motivate us to define the constraint satisfiability problem, which
allows us to consider all of the selected instructions as a whole, together with a variety of
system constraints. Specifically, it allows us to consider the coupon count ($m_i$) and the
coupon size $\text{NVM}(S_i)$ for each subset $S_i \subseteq \text{preSet}$, together with system constraints such as
the capacity of non-volatile memory used to store coupons computed by different instructions,
and the inter-procedural dependencies between these chosen instructions.

5.2 The Problem Statement

Our goal is to compute the optimal subset, denoted $S^* \subseteq \text{preSet}$, that satisfies the system
constraint. For ease of presentation, assume that $S$ represents a precomputation choice,
while $V(S)$ represents the value (or benefit) of precomputing $S$, and $C(S)$ represents the
cost of precomputing $S$. The optimization problem is defined formally as follows:

$$
S^* = \arg\max_{S \subseteq \text{preSet}} V(S) \quad \text{subject to} \quad C(S) \leq \text{maxNVM}
$$

In other words, the optimal subset is the subset $S$ that maximize the value $V(S)$ while
keeping the cost $C(S)$ under control. Recall that explicitly enumerating solutions would
lead to combinatorial explosion. Thus, we encode them symbolically using a set of logical
constraints and solve these constraints using an off-the-shelf SMT solver.

One advantage of the constraint based approach is flexibility in modeling various tradeoffs.
While it is easy to compute the coupon size or the coupon count individually, finding the
right combination may be hard due to the fact that they are inter-dependent.

Another advantage of our approach is flexibility in modeling the chain of influence; that
is, precomputing one instruction (e.g., $l_4$ of \texttt{gen_key} in Figure 4) may require precomputing
another instruction (e.g., $l_3$).

Yet another advantage is the ability to bound the total cost of storing coupons from
different instructions. As mentioned earlier, precomputing more instructions may not always
increase the storage cost. In Figure 4, if we precompute $l_3 - l_4$ but not $l_5$, we need to store
both \texttt{pub_key} and \texttt{keyHash}, the latter of which is an array of 108 bytes; but if we precompute
$l_3 - l_5$, we only need to store \texttt{pub_key}, which is an array of 32 bytes.

5.3 Defining the Value and Cost Functions

First, we define the energy saving (value) and storage overhead (cost).

5.3.1 Value

Since the value of precomputing one instruction may depend on which other instructions are
precomputed, we can only define it based on which other instructions are chosen. Since an
instruction $\text{inst}$ may be precomputed only if all its predecessors are precomputed, we define
the value of precomputing $\text{inst}$ based on the predecessor relation.

Let $S$ be the set of chosen instructions, and $v(\text{inst} \mid S)$ be the value of precomputing
$\text{inst}$ in the presence of $S$. We have

$$
v(\text{inst} \mid S) = \begin{cases} 
E(\text{inst}) & \text{if $\text{preds}(\text{inst}) \subseteq S$} \\
-\infty & \text{otherwise}
\end{cases}
$$
Here, $E(\text{inst})$ is the energy saved by precomputing $\text{inst}$, and $\text{preds}(\text{inst})$ is the set of all predecessors of $\text{inst}$ in the PDG. We use the large value $-\infty$ to avoid precomputing $\text{inst}$ before all of its predecessors in $\text{preds}(\text{inst})$ are precomputed.

With the values of precomputing individual instructions, we define the value of precomputing the entire set $S$ as follows:

$$V(S) = \sum_{\text{inst} \in S} v(\text{inst} \mid S).$$

For the example in Figures 4 and 8 (b), we have $V(\{l_2\}) = E(l_2)$. We also have $V(\{l_2, l_5\}) = -\infty$ since $l_5$ cannot be selected when its predecessors $l_3 - l_4$ are not selected.

### 5.3.2 Cost

Unlike the value $v(\text{inst})$, which depends only on the predecessors of $\text{inst}$, the cost of precomputing $\text{inst}$ depends also on its successors in the PDG.

Let $S$ be the set of chosen instructions, and $c(\text{inst} \mid S)$ be the cost of precomputing $\text{inst}$ in the presence of $S$. In Figure 4, for instance, we have

$$c(l_3 \mid S) = \begin{cases} 0 & \text{if } l_4, l_5 \in S \\ \text{NVM(keyHash)} & \text{otherwise} \end{cases}$$

and

$$c(l_4 \mid S) = \begin{cases} 0 & \text{if } l_2, l_3 \in S \\ +\infty & \text{otherwise} \end{cases}$$

That is, if $l_3 - l_5$ are selected, we do not need to store keyHash; but if $l_4 - l_5$ are not selected, we need to store keyHash. Thus, the cost of precomputing $l_3$ depends on if $(l_4 - l_5)$ are selected. Here, the large value $+\infty$ is used to avoid selecting instructions whose predecessors in the PDG are not selected.

With the costs of precomputing individual instructions, we define the cost of precomputing the entire set $S$ as follows:

$$C(S) = \sum_{\text{inst} \in S} c(\text{inst} \mid S).$$

### 5.4 Symbolic Encoding of the Constraints

We construct an SMT formula $\Psi = \Phi_{Dep} \land \Phi_{Value} \land \Phi_{Cost}$, where the subformula $\Phi_{Dep}$ captures the dependencies that we have computed in the previous section, $\Phi_{Value}$ captures the value constraint, and $\Phi_{Cost}$ captures the cost constraint. Thus, a satisfying assignment to $\Psi$ corresponds to $S^* \subseteq \text{preSet}$.

#### 5.4.1 Dependency Constraint

$\Phi_{Dep}$ encodes the dependency relations captured by edges of the inter-procedural PDG. Specifically, for each dependency edge $(n_1, n_2)$, we add a Boolean constraint $(-n_2 \lor n_1)$, where $n_1$ and $n_2$ are Boolean variables indicating whether these nodes are precomputed, and the constraint means that, if $n_2$ is true, then $n_1$ must also be true. Therefore, $n_2$ being precomputed implies that $n_1$ is also precomputed. Then, all these individual constraints are conjoined to form $\Phi_{Dep}$. As an example, consider the PDG in Figure 8 (b): the dependency constraints include $(-l_4 \lor l_3) \land (-l_4 \lor l_2) \land (-l_5 \lor l_4) \land (-l_9 \lor l_8)$. 
We now explain the subroutine
Transform\((P, PDG, preSet^*)\), which transforms the original program \(P\) to a new program \(P'\) to implement \(preSet^*\). Recall that in Figure 6, we gave an example of such a transformed program for W-OTS. There are two important properties of the program \(P'\): (1) it retains the overall function call structure in \(P\) and (2) it changes the body of each function to implement both the precomputation and online computation steps.
6.1 The Terminology

For each function \( f \) in the program \( P \), we must separate the precomputation instructions from
the online computation instructions. This leads to a partition of the program to segments,
\( \{ S_1, S_2, S_3, S_4, \ldots \} \), where \( S_i \) represents a precomputation segment and \( S_j \) represents an
online computation segment. A segment is a maximal set of instructions that may execute
continuously during precomputation or online computation.

Consider an example program \( P = \{ S_1, S_2, S_3, S_4 \} \) whose original execution order is
\( S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_4 \). In the transformed program \( P' \), however, the execution order must be
changed to \( S_1 \rightarrow S_3 \rightarrow S_2 \rightarrow S_4 \). In general, changes in the execution order lead to changes
in the data flow.

Before discussing changes in the data flow, we define the terminology.

- Let \( \text{def}(x) \) be an instruction that defines the value of variable \( x \), and \( \text{use}(x) \) be an
  instruction that uses the value. The two instructions may form a def-use pair.
- Given two segments \( S_i \) and \( S_j \), where \( \text{def}(x) \in S_i \) and \( \text{use}(x) \in S_j \), we represent the
data-flow edge (or def-use pair) as \( (S_i, S_j)(x) \).
- Let \( \text{Val}[x, S_i] \) denote the value of \( x \) at the end of executing the segment \( S_i \).
- A variable \( x \) is \textit{live} at a program location \( p \) if its value is used before it is defined again
  along some path from \( p \) to the program exit.

6.2 The Problem

Now, we show an example where changes in the execution order bring unexpected changes of
the data flow.

\textbf{Example 6.1.} In program \( P = \{ S_1, S_2, S_3, S_4 \} \), assume that \( \text{def}_1(x) \in S_1 \), \( \text{def}_2(x) \in S_2 \),
\( \text{use}(x) \in S_4 \). Due to the execution order, the def-use chain contains only \( \text{def}_2(x) \) and \( \text{use}(x) \),
meaning the value of \( x \) used in \( S_4 \) should be from \( \text{def}_2(x) \).

In the original execution order \( S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_4 \), the value \( \text{Val}[x, S_3] \) comes from
\( \text{def}_2(x) \), and the variable \( x \) is live in \( S_3 \), since \( \text{Val}[x, S_3] \) will be used in \( S_4 \).

In the new program, however, since the execution order is changed to \( S_1 \rightarrow S_3 \rightarrow S_2 \rightarrow S_4 \),
without our intervention, the value \( \text{Val}[x, S_3] \) would come from \( \text{def}_1(x) \), and the variable \( x \)
would \textit{no longer} be live in \( S_1 \). Such unexpected changes of the data flow may change the
semantics of the program. This is illustrated by Figure 10.

In general, it can be challenging to preserve the data flow while allowing change of
the execution order. While the technique of \textit{checkpointing} has been used in intermittent
computing systems [31, 47, 34], it cannot solve our problem because checkpointing does not
involve splitting a program into two parts and then executing the two parts in an interleaved
order. For the program in Example 6.1, specifically, checkpointing techniques would have
failed to preserve the data flow.

To understand why checkpointing would fail, consider the fact that variable \( x \) is live
at the end of \( S_2 \), at the end of \( S_3 \), and at the start of \( S_4 \). Checkpointing would insert
\( \text{nvms}_{\text{ST}}(\text{Val}[x, S_2]) \) at the end of \( S_2 \) and insert \( \text{nvms}_{\text{ST}}(\text{Val}[x, S_3]) \) at the end of \( S_3 \). It would
also insert \( \text{nvms}_{\text{LD}}(\text{Val}[x, S_2]) \) and \( \text{nvms}_{\text{LD}}(\text{Val}[x, S_3]) \) at the start of \( S_4 \).

When executing \( P' \) \( (S_1 \rightarrow S_3 \rightarrow S_2 \rightarrow S_4) \), \( \text{nvms}_{\text{LD}}(\text{Val}[x, S_3]) \) would over-write
\( \text{nvms}_{\text{LD}}(\text{Val}[x, S_2]) \); thus, the value of \( x \) used in \( S_3 \) would be \( \text{Val}(x, S_3) = \text{def}_1(x) \). However,
in the original program, the value of \( x \) used in \( S_4 \) is \( \text{def}_2(x) \).

The fundamental reason why checkpointing techniques are ill-suited for our project is
that the \textit{liveness} property of a program variable, which forms the theoretical foundation of
checkpointing techniques, is not preserved by the split of a program into the precomputation and online computation parts. Thus, instead of relying on the *liveness* property, our method relies on the *def-use* relations.

### 6.3 The Baseline Method

We first present the baseline method using the *def-use* relations, and then present the optimized method in the next subsection.

Since we treat each segment as an atomic unit during transformation, we only need to consider the *def-use* relations between segments. Thus, whenever two segments have *def-use* relations, there can only be three scenarios:

(I) \( \langle S_i, S_j \rangle \), meaning both are precomputation segments;

(II) \( \langle S_i, \tilde{S}_j \rangle \), meaning \( S_i \) is a precomputation and \( \tilde{S}_j \) is an online computation; and

(III) \( \langle \tilde{S}_i, \tilde{S}_j \rangle \), meaning both are online computation segments.

The fourth scenario, \( \langle \tilde{S}_i, S_j \rangle \), is impossible due to our method for computing \( \text{preSet} \).

In other words, a *use* in a precomputation segment always comes from a *definition* in a precomputation segment, whereas a *use* in an online computation segment may come from a *definition* in a precomputation or an online computation segment.

Furthermore, it suffices to handle only type (II) case \( \langle \tilde{S}_i, \tilde{S}_j \rangle \), because for the other two cases, the value can be propagated directly between the two segments of the same type.

To maintain the *def-use* chains between precomputation and online computation segments in the type (II) case, we must insert \( \text{nvmsLD} \) and \( \text{nvmsST} \) instructions at the proper *def* and *use* locations.

Thus, our baseline method can be summarized as follows: For each data-flow edge \( \langle S_i, \tilde{S}_j \rangle(x) \), we insert \( \text{nvmsST}(\text{Val}[x, S_i]) \) at the end of \( S_i \), and insert \( \text{nvmsLD}(\text{Val}[x, S_i]) \) at the start of \( \tilde{S}_j \).

Recall the scenario shown in Example 6.1, where the *def-use* chain contains only *def* \( x \) and *use* \( x \). According to our baseline method, no NVM operation needs to be added, since the *def-use* is of the type (III). The value of \( x \) used in \( \tilde{S}_4 \) comes directly from *def* \( x \).
6.4 The Optimized Method

Now, we present an optimization to avoid redundant NVM operations inserted by the baseline method. To understand why some of the NVM operations inserted by our baseline method may be redundant, consider the following example.

Example 6.2. In \( \{S_1, S_2, S_3, S_4\} \), assume that def\( (x) \in S_1 \), use\( _1(x) \in S_2 \), use\( _2(x) \in S_4 \), and the def-use chain contains both def\( (x) – \text{use}_1(x) \) and def\( (x) – \text{use}_2(x) \). Our baseline method would insert

\[
\begin{align*}
& \text{nvm\_ST}(\text{Val}[x, S_1]) \text{ after } S_1 \text{ (twice);} \\
& \text{nvm\_LD}(\text{Val}[x, S_1]) \text{ before } S_2; \\
& \text{nvm\_LD}(\text{Val}[x, S_1]) \text{ before } S_4.
\end{align*}
\]

However, executing \text{nvm\_LD}(\text{Val}[x, S_1]) \text{ before } S_4 is redundant because the value of \( x \) can be propagated directly from \( S_2 \).

To avoid the redundant operations, we should insert \text{nvm\_LD} of a def\( (x) \) at the start of the earliest online computation segment where def\( (x) \) is available. For the program in Example 6.2, the earliest segment is \( S_2 \), which means we should insert \text{nvm\_LD}(\text{Val}[x, S_1]) \text{ right before } S_2.

Thus, our optimized method can be summarized as follows: For each data-flow edge \( \langle S_i, S_j \rangle(x) \) that we have not inserted \text{nvm\_ST}(\text{Val}[x, S_i]) \text{ after } S_i, \text{ insert } \text{nvm\_ST}(\text{Val}[x, S_i]) \text{ after } S_i \text{ and insert } \text{nvm\_LD}(\text{Val}[x, S_i]) \text{ before } S_{i+1}.

To understand the benefit of this optimization, let us compare the data flows of the following two programs. If, for example, in the original program, \text{Val}[x, S_1] \text{ is available (and not killed) in the range}

\[ \text{end}[S_1] \to S_{i+1} \to S_{i+2} \to S_{i+3} \to \cdots \]  

and in the transformed program, \text{Val}[x, S_1] \text{ is available (and not killed) in the range}

\[ \text{end}[S_1] \to S_{i+2} \to S_{i+4} \to S_{i+6} \to \cdots \]  

and \text{nvm\_LD} Val[x, S_1] \text{ has been inserted before } S_{i+1} \text{ in the transformed program, the loaded value will also be available in the entire range}

\[ S_{i+1} \to S_{i+3} \to S_{i+5} \to S_{i+7} \to \cdots \]  

Therefore, we can avoid the other (redundant) \text{nvm\_LD} operations before \( S_{i+3} \cdots S_{i+7} \).

6.5 The Transformation Algorithm

To sum up, our optimized method for transforming each function \( f \) of the original program based on \text{preSet}^+ \text{ is presented in Algorithm 3.}

Our method first partitions the instructions in function \( f \) to precomputation segments \( \{S_i\} \) and online computation segments \( \{S_j\} \). Next, it inserts \text{if-condition} to each segment using the two flags, to differentiate the three use cases. Finally, for each data-flow edge \( \langle S_i, S_j \rangle(x) \), it inserts NVM operations to store the value of variable \( x \) computed in \( S_i \) (the coupon) at the end of segment \( S_i \).

While in the baseline method, the coupon is loaded from NVM at the start of \( S_j \), in the optimized method, it is loaded at the start of the online computation segment \( S_{i+1} \). Loading the coupon earlier provides the opportunity to eliminate many redundant NVM operations.
Algorithm 3: Transforming a function \( f \) in program \( P \) based on \( \text{preSet}^* \).

1. Partition \( f \) into segments \( \{S_i\} \) and segments \( \{\tilde{S}_j\} \);
2. Add \text{if-condition} to each segment using \text{precom\_flag} and \text{online\_flag};
3. \text{foreach} data-flow edge denoted \( (S_i, \tilde{S}_j)(x) \) do
   4. \text{if} there is no \text{nvm\_ST}(Val[x, S_i]) after segment \( S_i \) \text{then}
      5. Add \text{nvm\_ST}(Val[x, S_i]) after \( S_i \);
      6. Add \text{nvm\_LD}(Val[x, S_i]) before \( \tilde{S}_{i+1} \);
   end
4. end

7 Experiments

We have implemented our method in a software tool, named \text{COUPONMAKER}, which builds upon the LLVM compiler platform \cite{29} and the Z3 SMT solver \cite{11}. We leverage LLVM to parse the C code of the original program, conduct inter-procedural dependency analysis and implement the semantic-preserving transformation. We use Z3 to solve the constraint satisfiability subproblems. In total, our implementation adds 1,852 lines of C++ code.

Our tool generates the LLVM bit-code of the optimized program as output, which in turn is compiled to machine code for the MSP430 MCU. To evaluate the performance of the optimized program, we use the cycle-accurate emulator MSPSim \cite{38}. Specifically, we use MSPSim to compute the latency and energy consumption of the optimized program, and compare them with the latency and energy consumption of the original program.

7.1 Benchmarks

We evaluated \text{COUPONMAKER} on 26 benchmark programs, which are C programs implementing lightweight cryptographic protocols. In total, they have 31,113 lines of C code.

Table 1 shows the statistics, where Columns 1-3 show the name, category, and source of each program, and Column 4 shows the number of lines of code (LoC).

The benchmark programs fall into two groups. The first group consists of programs that compute one-time signatures (W-OTS and Lamport) and the second group consists of programs that implement block-ciphers (e.g., AES and Camellia). A one-time signature scheme allows a message to be signed using a fresh key pair. Since any fresh key pair may work for any message, it is possible to precompute many key pairs and store them as coupons for future use. A block cipher divides a message into fixed-size blocks and then encrypts each block. For example, AES-CTR encrypts each block by first encrypting a counter value and then XOR-ing it with the plaintext to generate the ciphertext. The precomputing function is responsible for encrypting the counter value. Since there are multiple blocks, different counter values need to be encrypted. For each of the eight block-cipher programs, we also configure it in three different modes, marked by suffixes -OFB, -CFB, and -CTR, respectively.

Our experiments were conducted on a computer with 2 GHz Intel Core i5 CPU and 16 GB memory. These experiments were designed to answer the following questions:

- Is \text{COUPONMAKER} efficient in optimizing the benchmark programs?
- Are the optimized programs better than the original programs in terms of both energy efficiency and latency?

7.2 Performance of the Optimization Tool

Table 2 shows the results of evaluating the optimization tool. Column 1 shows the benchmark name. Column 2 shows the total running time in seconds. Column 3 shows the size of preSet, which is the set of instructions that may be precomputed. Columns 4-5 compare the size of the original and optimized programs, where the size is measured in the number of bytes of the LLVM bit-code. Columns 6-8 show the details of the coupons stored in non-volatile memory, including the number of coupons, and the total bytes, and whether the coupons may be precomputed multiple times (copies).

Specifically, ∞ in the last column means the coupons may be precomputed an unlimited number of times, while 1 means they may be precomputed only once.

For programs that compute one-time signatures (W-OTS and Lamport), a theoretically unbounded number of signatures (coupons) may be precomputed. For block-cipher programs in the -OFB mode, the ciphertext of the first block may also be precomputed as many times as possible (after the first block becomes available), and in the -CNT mode, the counter CNT may be incremented as many times as possible and then pre-encrypted for future use.

For block-cipher programs in the -CFB mode, however, precomputation can only be done once per block, i.e., after the current block arrives.

The results show that our method is able to analyze, optimize, and transform all benchmark programs quickly. The total running time is limited to a few seconds. Moreover, the size of the program before and after optimization changes moderately. Furthermore, the number and size of precomputed coupons are significant for all programs.

7.3 Performance of the Optimized Programs

Table 3 shows the result of evaluating the performance of the optimized programs. These results were obtained using the MSPSim tool for MSP430FR599x [24]. Since MSPSim requires the programs to be executed under concrete test inputs, for one-time signature programs (W-OTS and Lamport), we obtain the test inputs by signing a fixed-length message; for block-cipher programs, we obtain the test inputs by encrypting sensor data that represent a sequence of temperature measurements.

In the result table, Column 1 shows the benchmark name. Column 2 shows the energy (µJ) consumed by the original program. Columns 3-4 show the energy (µJ) consumed by the optimized program, which is divided into the precomputing and online steps. Recall that in energy-harvesting applications, energy reported in the E(pre) column is considered to be free. Thus, the ratio in Column 5 represents the actual performance improvement.

</tbody>
</table>

The results show that the optimized programs significantly outperform the original programs in terms of energy efficiency. The improvement ranges from 2.3X to 36.7X. We also compared the latency of the original and optimized programs and observed a similar improvement; we omit the result table due to space limit. Overall, these results show that our method is effective in reducing the latency and energy cost.

7.4 Impact of the Precomputation Policy

Finally, we evaluate the impact of precomputation policy by computing the energy saving per unit use of non-volatile memory storage, measured by $q_f = (E(ori) - E(on))/\text{Size}(coupon)$, where $q_f$ stands for quality factor. The results are shown in Figure 11, where the $x$-axis is the index of the array of benchmark programs and the $y$-axis is the quality factors ($q_f$) achieved by the baseline and optimized methods for program transformation (Section 6).

In this figure, blue bars (optimal) correspond to the optimized precomputation policy ($\text{preSet}^*$), while orange bars (baseline) corresponds to the initial precomputation policy ($\text{preSet}$). Here, a higher $q_f$ value corresponds to a better result. Overall, the optimized precomputation policy leads to significantly better results.

For W-OTS, $q_f(\text{optimal})$ is also significantly higher than $q_f(\text{baseline})$. However, the $q_f$ values for W-OTS are not included in the figure, to avoid making the rest of the bar chart less readable. This is because W-OTS takes several orders-of-magnitude more clock cycles than the other programs, and thus has a much higher $q_f$ value.

8 Related Work

While prior work has shown the feasibility of optimizing energy-harvesting applications using precomputation [46], optimization is performed manually; to the best of our knowledge, this is the first automated optimization method. Compared to Suslowicz et al. [46], in particular, our method can complete all of the optimization work with comparable performance. Moreover, our method can support additional constraints for optimization, which the manual method cannot deal with easily. Since our method is designed to preserve the original program semantics, it is not meant for scenarios where the underlying algorithms are intended to be rewritten according to some mathematical rules [4, 5] – automation for such transformation is beyond the scope of this work.

Our method differs from the large number of intermittent computing techniques aimed to improve general-purpose systems with a strong and yet unstable power supply; these techniques [42, 34, 31, 47] focus on recovering from power loss using checkpointing, avoiding the costly register accesses, or reducing the cost for loop-heavy programs [18, 17]. There are also techniques for robustly supporting peripherals [45, 35]. However, none of them considers the scenario where ambient energy source is ample but the computing device is idle, let alone leveraging precomputation to reduce the energy cost.

There are also techniques for programming transiently-powered computers with both volatile and non-volatile memory, for example, by leveraging the application’s memory access patterns to manually optimize data placement [9, 31, 33], or mapping of code sections to either volatile or non-volatile memory [25] based on where the optimal energy consumption
could be achieved. There are also efficient checkpointing techniques [21, 1] for CPUs with fully non-volatile main memory. However, none of them focuses on automated program optimization based on precomputation.

Constraint solving based techniques are widely used for program verification, repair and optimization. For example, they have been used to debug concurrent software [27, 23] and optimize the quality of embedded software [13]. They have also been used to mitigate side-channel vulnerabilities [48, 19, 51, 49], including power side-channel leaks [53, 50]. However, power side-channel mitigation focuses on eliminating tiny fluctuations in power consumption that are also secret-dependent [14], instead of reducing the power consumption itself.

While our focus in this work is on optimizing software for energy-harvesting applications, the underlying ideas may be applied to other applications of similar nature, e.g., precomputation for Trusted Authority (TA) in the context of multi-party computation (multi-party learning and predicting[52, 16]). Since the application domain is significantly different, to deal with software used in such applications, our LLVM based implementation may need to be updated accordingly – we leave this for future work.

9 Conclusion

We have presented a constraint based method for optimizing the energy efficiency of software code running on devices powered by electricity harvested from the environment. Our method is sound and fully automated. It relies on static program analysis to identify instructions that may be precomputed, constraint solving to compute an optimal subset, and compiler transformation to generate the new software code. Our experimental evaluation on a large number of benchmark programs shows that the proposed method can handle all of the benchmark programs quickly, and the optimized programs significantly outperform the original programs in terms of both energy efficiency and latency.
